

Laboratory observations of magnetic reconnection resulting from multiscale instability cascade

A. L. Moser & P. M. Bellan
Caltech

Overview

- ▶ How does ideal MHD plasma couple to microscale?
- ▶ How does it happen so fast (impulsively)?

Overview

- ▶ How does ideal MHD plasma couple to microscale?
- ▶ How does it happen so fast (impulsively)?
→ Instability of an instability

Caltech experiment setup

End dome with electrodes

Magnetic field coil

$T \sim 1 - 2 \text{ eV}$, $n \sim 10^{21-22} \text{ m}^{-3}$, $B \sim 0.1 \text{ T}$

Current-driven ideal MHD kink instability

Kruskal-Shafranov instability criteria:

$$q(a) = \frac{2\pi a B_z(a)}{L B_\phi(a)} < 1$$

In experimental parameters:

$$\lambda_{gun} = \frac{\mu_0 I_{gun}}{\Psi_{gun}} > \frac{4\pi}{L}$$

Kink instability growth rate: Linear or exponential

Rayleigh-Taylor instability

On trailing edge of outward
accelerating filament
 $\lambda \approx 2 \text{ cm}$

Calculate effective gravity at time of Rayleigh-Taylor onset

In this case, offset is:

$$\xi(t) = 6 \times 10^{-3} \exp[8 \times 10^5 (t - t_0)]$$

Rayleigh-Taylor first appears at $t = 24 \mu\text{s}$; acceleration is:

$$g(t) = (8 \times 10^5)^2 \xi(t) \approx 4 \times 10^{10} \text{ m/s}^2$$

Calculate predicted Rayleigh-Taylor growth rate

R-T growth rate:

$$\gamma^2 = gk \left(\frac{\rho_2 - \rho_1}{\rho_2 + \rho_1} - \frac{2(\mathbf{k} \cdot \mathbf{B})^2}{\mu_0 (\rho_2 + \rho_1) gk} \right)$$

Assumptions:

$$\mathbf{k} \cdot \mathbf{B} = 0 \quad (\text{fastest growing mode})$$

$$\rho_2 \gg \rho_1 \quad (\text{density in filament much greater than just outside filament})$$

R-T growth rate becomes:

$$\begin{aligned} \gamma^2 &= gk \\ &\approx 4 \times 10^{10} \frac{2\pi}{0.02} \implies \gamma \approx \boxed{3 \times 10^6 \text{ s}^{-1}} \end{aligned}$$

Estimate observed Rayleigh-Taylor growth rate

$$t_1 = 24 \mu\text{s}$$
$$A_1 \approx 0.5 \text{ cm}$$

$$t_2 = 25 \mu\text{s}$$
$$A_2 \approx 1.5 \text{ cm}$$

$$\frac{A_2}{A_1} = \exp[\gamma(t_2 - t_1)]$$
$$\frac{1.5}{0.5} = \exp[\gamma(1 \times 10^{-6})] \implies \gamma \approx \boxed{1 \times 10^6 \text{ s}^{-1}}$$

Plasma reconnects after Rayleigh-Taylor instability

Burst of EUV radiation

Excitation in whistler wave frequency range

Non-MHD scale at time of reconnection

$$\begin{aligned}\frac{v_d}{v_A} &= \frac{J_z}{nq} \frac{\sqrt{\mu_0 n m_i}}{B} \approx \frac{\mu_0 J_z}{B_z} \left(\frac{c}{\omega_{pi}} \right) \\ &\approx \frac{4\pi}{\lambda_z} \left(\frac{c}{\omega_{pi}} \right) \\ &\approx \mathcal{O}(1)\end{aligned}$$

MHD assumes $\frac{v_d}{v_A} \ll 1$, so this is non-MHD scale

Rayleigh-Taylor is necessary but not sufficient for reconnection

Argon

$$c/\omega_{pi} = 1 \text{ cm}$$

$$d = 0.5 \text{ cm}$$

Reconnection observed

Nitrogen

$$c/\omega_{pi} = 0.5 \text{ cm}$$

$$d = 0.4 \text{ cm}$$

Reconnection observed

Hydrogen

$$c/\omega_{pi} = 0.2 \text{ cm}$$

$$d = 0.7 \text{ cm}$$

No reconnection
observed

Conclusion

- ▶ Plasma starts on ideal MHD scale
- ▶ Kink instability
- ▶ Non-inertial frame, effective gravity
- ▶ Rayleigh-Taylor instability
- ▶ Magnetic reconnection when plasma on “microscopic” scale

Question: What determines whether the kink amplitude grows linearly or exponentially?

Non-MHD scale at time of reconnection: details

The magnetic field and wavevector have form

$$\mathbf{B} = B_\phi \hat{\phi} + B_z \hat{z} \quad \text{and} \quad \mathbf{k} = k_\phi \hat{\phi} + k_z \hat{z} = \frac{m}{r} \hat{\phi} + \frac{2\pi}{\lambda_z} \hat{z}.$$

Using $\mathbf{k} \cdot \mathbf{B} = 0$, these equations combine to give us

$$\mathbf{k} \cdot \mathbf{B} = \frac{m}{r} B_\phi + \frac{2\pi}{\lambda_z} B_z = 0 \Rightarrow B_\phi = \frac{2\pi r}{\lambda_z} B_z.$$

Ampère's law gives us

$$\mu_0 J_z = \frac{1}{r} \frac{\partial}{\partial r} (r B_\phi),$$

combining these two gives

$$\frac{J_z}{B_z} = \frac{4\pi}{\mu_0 \lambda_z}.$$
